

1) a) When a TCP connection is established via a 3-way handshake, the transport layer keeps track of all the required information:-
{ Source & destination IPs & ports. Hence, when send a TCP packet the OS already knows where to send it.

With UDP however, no such information is stored. Hence, you need to specify to the OS where you are sending the packet.

b) A UDP socket is fully identified by the a tuple consisting of a the destination IP & destination port.

A TCP socket is identified by the source IP, source port, destination IP & destination port.

c) Yes, as the transport layer will ~~can~~ identify the port 8080 host A and deliver the segment to that socket regardless of who sent it.

To process at host A can determine ~~the~~ who sent the segment by looking at the source IP & port of the incoming segment.

2) a) Although both use TCP connections, in HTTP 1.0 these connections are not persistent. ~~For~~ They are established & closed after every request.

HTTP 1.1 uses persistent connections, allowing multiple requests ~~after~~ over ~~one~~ connection.

b) If addressed:-

- Inefficient use of a connection, establishing a new one for every request.

- Inability to pipeline, each request has to be completed before a subsequent one can be made.

2c) The 2nd lot of time is saved by avoiding the need to do a 3-way handshake for every request, leading to faster page loads, less CPU load & more efficient communication. The ability to pipeline makes that even faster as requests can be made simultaneously.

3) Application designers can exploit TCP by opening multiple ~~the~~ parallel TCP connections. Allowing their application to grab more ~~band~~ bandwidth at the expense of other data flows.

4)

rdt-rcv(rcv pkt) && not corrupt(rcv pkt)
&& has-seq0(rcv pkt)

extract(rcv pkt, data)
deliver-data(data)
snd pkt = make pkt(Ack, 0, checksum)
udt-send(snd pkt)

Wait for 0 from below

rdt-rcv(rcv pkt)
&& (corrupt 1)
|| && has-seq1(rcv pkt)

snd pkt = make pkt(Ack, 1, checksum)
udt-send & send pkt

rdt-rcv(rcv pkt) && not corrupt
&& has seq 1(rcv pkt)

extract(rcv pkt, data)
deliver-data(data)
snd pkt = make pkt(Ack, 1, checksum)
udt-send = (snd pkt)

Wait for 1 from below

rdt-rcv(rcv pkt)
&& (corrupt 1)
&& has seq 0(pkt)

snd pkt = make pkt
(Ack, 0)
checksum

udt-send(snd pkt)

5) A potential solution is to use a min-heap to track the timeout times for the sent packets. Maintain a single timer to track the ~~smallest~~ earliest timeout. On expiry, process packets that have expired & resend them, reset their timers. & use the hardware timer for the next earliest expiry.

a) DS:- Min-heap or some sorted structure
Maybe a hashtable to ~~track~~ associate timers & packet ID

Computation:- Insert/delete on send/Ack fmping, recalculation of timer

Memory:- Storing timer for each unacked packet

b) A simpler solution can be to only track the oldest un-Ack'd packet since all earlier ones are ack'd.

If we reset the timer every time a packet is sent, it will be reset for every new packet, causing the oldest unacked's ~~to~~ be retried to be delayed until all have been sent.

When the oldest packet is Ack'd we can move our ~~search~~ window forward to the next unacked packet & reset the timer, restarting the process.
